(Received 5 February 2007; published 11 May 2007)

We report on the unusual nature of the ν = 0 state in the integer quantum Hall effect (QHE) in graphene and show that electron transport in this regime is dominated by counterpropagating edge states. Such states, intrinsic to massless Dirac quasiparticles, manifest themselves in a large longitudinal resistivity ρxx ≥ ℏ/2e2, in striking contrast to ρxx behavior in the standard QHE. The ν = 0 state in graphene is also predicted to exhibit pronounced fluctuations in ρxy and ρxx and a smeared zero Hall plateau in σxy, in agreement with experiment. The existence of gapless edge states puts stringent constraints on possible theoretical models of the ν = 0 state.

DOI: 10.1103/PhysRevLett.98.196806 PACS numbers: 81.05.Uw

The electronic properties of graphene [1], especially the anomalous integer quantum Hall effect (QHE) [2,3], continue to attract significant interest. Graphene features QHE plateaus at half-integer values of σxy = (±1/2, ±3/2, . . . )4e2/h where the factor 4 accounts for double valley and double spin degeneracy. The “half-integer” QHE is now well understood as arising due to unusual charge carriers in graphene, which mimic massless relativistic Dirac particles. Recent theoretical efforts have focused on the properties of spin- and valley-split QHE at low filling factors [4–9] and fractional QHE [10]. Novel states with dynamically generated excitonlike gap were conjectured near the Dirac point [11–13]. However, experiments in ultrahigh magnetic fields [14] have so far revealed only additional integer plateaus at ν = 0, ±1 and ±4, which were attributed to valley and spin splitting.

The most intriguing QHE state is arguably that observed at ν = 0. Being intrinsically particle-hole symmetric, it has no analog in semiconductor-based QHE systems. Interestingly, while it exhibits a steplike feature in σxy, the experimentally measured longitudinal and Hall resistance [14] (ρxx and ρxy) display neither a clear quantized plateau nor a zero-resistance state, the hallmarks of the conventional QHE. This unusual behavior was attributed to sample inhomogeneity [14] and remains unexplained. In this Letter, we show that such behavior near the Dirac point is in fact intrinsic to Dirac fermions in graphene and indicates an opening of a spin gap in the energy spectrum [4]. The gap leads to counter-circulating edge states carrying opposite spin [4,5] which result in interesting and rather bizarre properties of this QHE state. In particular, even in the complete absence of bulk conductivity, this state has a nonzero ρxx ≥ ℏ/2e2 (i.e., the QHE state is dissipative) whereby ρxx can change its sign as a function of density without exhibiting a plateau.

We start by reviewing the experimental situation near ν = 0. Our graphene devices were fabricated as described in Ref. [1] and fully characterized in fields B up to 12 T at temperatures down to 1 K, revealing the behavior characteristic of single-layer graphene [2]. Several devices were then investigated in B up to 30 T, where, besides the standard half-integer QHE sequence, the ν = 0 plateau becomes clearly visible as an additional step in σxy (Fig. 1). We note, however, that the step is not completely flat, and there is no clear zero-resistance plateau in ρxy. Instead, ρxy exhibits a fluctuating feature away from zero which seems trying to develop in a plateau [Fig. 1(b)]. In some devices ρxy passed through zero in a smooth way without fluctuations.) Moreover, ρxx does not exhibit a zero-resistance state either. Instead, it has a pronounced peak near zero ν which does not split in any field. The value at the peak grows from ρxx = ℏ/4e2 in zero B to ρxx > 45 kΩ at 30 T [see inset of Fig. 1(b)].

The absence of both hallmarks of the conventional QHE could cast doubt on the relation between the observed extra step in σxy and an additional QHE plateau. However, the described high-field behavior near ν = 0 was found to be universal (reproducible for different samples, measurement geometries and magnetic fields above 20 T). It is also in agreement with that reported in Ref. [14]. Moreover, one can generally argue that the QHE at ν = 0 cannot possibly exhibit the usual hallmarks. Indeed, ρxx cannot exhibit a zero-resistance state simultaneously with ρxy passing through zero due to the carrier-type change because zero in both ρxx and ρxy would indicate a dissipationless (superconducting) state.

To analyze the anomalous behavior of the high-field QHE, we note that all microscopic models near the Dirac point can be broadly classified in two groups, QH metal and QH insulator, as illustrated in Fig. 2. Transport properties in these two cases are very different. The QH insulator [Fig. 2(b)] is characterized by strongly temperature dependent resistivity diverging at low T. The metallic T dependence observed at ν = 0 clearly rules out this scenario. In the QH metal [Fig. 2(a)], a pair of gapless edge excitations [Fig. 2(a)] provides dominant contribution to...
FIG. 1 (color online). Longitudinal and Hall conductivities $\sigma_{xx}$ and $\sigma_{xy}$ (a) calculated from $\rho_{xx}$ and $\rho_{xy}$ measured at 4 K and $B = 30$ T (b). The $\nu = 0$ plateau in $\sigma_{xy}$ and the double-peak structure in $\sigma_{xx}$ arise mostly from strong density dependence of $\rho_{xx}$ peak (green trace shows $\sigma_{xy}$ for another sample). The upper inset shows one of our devices. The lower insets show temperature and magnetic field dependence of $\rho_{xx}$ near $\nu = 0$. Note the metallic temperature dependence of $\rho_{xx}$.

$\sigma_{xx}$, while transport in the bulk is suppressed by an energy gap. Such a dissipative QHE state will have $\sigma_{xx} \sim e^2/h \gg \sigma_{xy}$, i.e., nominally small Hall angle and apparently no QHE. The roles of bulk and edge transport here effectively interchange: The longitudinal response is due to edge states, while the transverse response is determined mainly by the bulk properties.

FIG. 2 (color online). Excitation dispersion in $\nu = 0$ QH state with and without gapless chiral edge modes, (a) and (b) respectively. Case (a) is realized in spin-polarized $\nu = 0$ state [4], while case (b) occurs when symmetry is incompatible with gapless modes, for example, in valley-polarized $\nu = 0$ state conjectured in Ref. [14]. In the latter state a gap opens at branch crossing due to valley mixing at the sample boundary.

From a general symmetry viewpoint advanced in Ref. [15] the existence of counter-circulating gapless excitations is controlled by $Z_2$ invariants, protecting the spectrum from gap opening at branch crossing. In the spin-polarized QHE state [4] this invariant is given by $\sigma_\epsilon$. While for other $\nu = 0$ QHE states [11–13] such invariants are not known, any viable theoretical model must present a mechanism to generate gapless edge states.

The metallic temperature dependence indicates strong dephasing that prevents onset of localization. To account for this observation, we suppose that the mean free path along the edge is sufficiently large, such that local equilibrium in the energy distribution is reached in between backscattering events. For that, the rate of inelastic processes must exceed the elastic backscattering rate: $\nu_{\text{inel}} \gg \nu_{\text{el}}$. This situation occurs naturally in the Zeeman-split QHE [4], since backscattering between chiral modes carrying opposite spins is controlled by spin-orbital coupling which is small in graphene.

In the depHased regime, the chiral channels are described by local chemical potentials, $\phi_{1,2}(x)$, whose deviation from equilibrium is related to currents:

$$I_1 = \frac{e^2}{h} \phi_1, \quad I_2 = \frac{e^2}{h} \phi_2, \quad I = I_1 - I_2,$$

where $I$ is the total current on one edge. In the absence of backscattering between the channels the currents $I_{1,2}$ are conserved. In this case, since the potentials $\phi_{1,2}$ are constant along the edge, transport is locally nondissipative, similar to the usual QHE [16].

The origin of longitudinal resistance in this ideal case can be traced to the behavior in the contact regions. [Note the resemblance of each edge in Fig. 3(a) with two-probe measurement geometry for the standard QHE.] We adopt the model of thermal reservoirs [17] which assumes full mixing of electron spin states within Ohmic contacts [see Fig. 3(b)]. With currents $I_1, I_2$ flowing into the contact, and equal currents $I_{1,2}^{(\text{out})} = \frac{1}{2}(I_1 + I_2)$ flowing out, the potential of the probe is $V_{\text{probe}} = \frac{e}{2} I_{1,2}^{(\text{out})}$. Crucially, using Eq. (1), there is a potential drop across the contact.

FIG. 3 (color online). (a) Schematic of transport in a Hall bar with voltage probes. Chiral edge states carrying opposite spin, Eqs. (3), are denoted by red and blue. Transport through the bulk is indicated by dotted lines. (b) Voltage probe in a full spin mixing regime [17] measures $V_{\text{probe}} = \frac{e}{2} (I_1 + I_2)$. Note finite voltage drop across the probe, Eq. (2).
\[ \Delta \varphi = \frac{h}{2e^2} (I_1 - I_2), \]  

(2)
equally for \( \varphi_1 \) and \( \varphi_2 \). The voltage between two contacts positioned at the same edge [see Fig. 3(a)] is equal to \( V_{xx} = \frac{h}{2e} I \), which gives a universal resistance value [4]. This is in contrast with the usual QHE where there is no voltage drop between adjacent potential probes [16,17].

The longitudinal resistance increases and becomes nonuniversal in the presence of backscattering. It can be described by transport equations for charge density

\[ \begin{align*}
\partial_t n_1 + \partial_x \varphi_1 &= \gamma (\varphi_2 - \varphi_1), \\
\partial_t n_2 - \partial_x \varphi_2 &= \gamma (\varphi_1 - \varphi_2),
\end{align*} \]

(3)

where \( \gamma^{-1} \) is the mean free path for 1d backscattering between modes 1 and 2, and \( n_{1,2} \) are compressibilities of the modes 1 and 2. In a stationary state, Eqs. (3) have an integral \( \mathbf{I} = \varphi_1 - \varphi_2 \) which expresses conservation of current \( I = \frac{\gamma}{\epsilon} \mathbf{I} \). The general solution in the stationary current-carrying state is \( \varphi_{1,2}(x) = \varphi_{1,2}^{(0)} - \gamma \chi \mathbf{I} \).

For the Hall bar geometry shown in Fig. 3(a), taking into account the contribution of voltage drop across contacts, Eq. (2), we find the voltage along the edge \( V_{xx} = (\gamma L + 1) \mathbf{I} \), where \( L \) is the distance between the contacts. In the absence of transport through the bulk, if both edges carry the same current, the longitudinal resistance is

\[
R_{xx} = (\gamma L + 1) \frac{h}{2e^2}, \quad \rho_{xx} = (w/L)R_{xx},
\]

(4)

with \( w/L \) the aspect ratio. From \( \rho_{xx} \) peak value (Fig. 1) we estimate \( \gamma w \approx 2.5 \), which gives the backscattering mean free path of 0.4 \( \mu \text{m} \). The metallic \( T \) dependence of \( \rho_{xx} \) signals an increase of scattering with \( T \) [Fig. 1(b) inset]. Similarly, \( \rho_{xx} \) growing with \( B \) is explained by enhancement in scattering due to electron wave function pushed at high \( B \) towards the disordered boundary.

An important consequence of the 1d edge transport is the enhancement of fluctuations caused by position dependence of the scattering rate \( \gamma(x) \). Solving for the potentials at the edge,

\[
\varphi_{1,2}(x) = \varphi_{1,2}^{(0)} - \frac{1}{\gamma} \int_0^x \gamma(y) dy,
\]

(5)

we see that the fluctuations in the longitudinal resistance scale as a square root of separation between the contacts:

\[
\delta V_{xx} = \int_{x_1}^{x_2} \delta \gamma(y) dy, \quad \delta R_{xx} \sim (h/e^2)\sqrt{L/a},
\]

where \( a \approx \gamma^{-1} \) is a microscopic length which depends on the details of spatial correlation of \( \gamma(x) \). Similar effect leads to fluctuations of the Hall voltage about zero average value at \( \nu = 0 \). Treating the fluctuations of the potential at each edge, Eq. (5), as independent, we estimate \( \delta R_{xy} \sim (h/e^2)\sqrt{L/a} \), where \( L \) is the bar length.

These fluctuations manifest themselves in noisy features in the transport coefficients near \( \nu = 0 \), arising from the dependence of the effective scattering potential on electron density. Such features can indeed be seen in \( \rho_{xy} \) and \( \rho_{xx} \) around \( \nu = 0 \) [Fig. 1(b)]. As discussed below, away from \( \nu = 0 \) bulk transport can short-circuit the edge transport. This will lead to suppression of fluctuations in \( \rho_{xx} \) and \( \rho_{xy} \) away from \( \nu = 0 \), in agreement with the behavior of the fluctuations in Fig. 1(b).

Another source of asymmetry in voltage distribution on opposite sides of the Hall bar at zero \( \nu \) is the potential drop on a contact, Eq. (2). This quantity can be nonuniversal for imperfect contacts, leading to finite transverse voltage. Such an effect can be seen in \( \rho_{xy} \) data in Fig. 1 near \( \nu = 0 \), where Hall effect in a pristine system would vanish.

To describe transport properties at finite densities around \( \nu = 0 \), we must account for transport in the bulk. This can be achieved by incorporating in Eq. (3) the terms describing the edge-to-bulk leakage:

\[
\begin{align*}
\partial_t \varphi_1 &= \gamma (\varphi_2 - \varphi_1) + \lambda (\psi_1 - \varphi_1), \\
-\partial_t \varphi_2 &= \gamma (\varphi_1 - \varphi_2) + \lambda (\psi_2 - \varphi_2),
\end{align*}
\]

(6)

where \( \psi_{1,2} \) are the up- and down-spin electrochemical potentials in the bulk near the boundary. Transport in the interior of the bar is described by tensor current-field relations with the longitudinal and Hall conductivities \( \sigma_{xx}^{(1)}, \sigma_{xy}^{(1)} \) for each spin component. Combined with current continuity, these relations yield 2d Laplace’s equation for the quantities \( \psi_{1,2} \), with boundary conditions supplied by current continuity at the boundary:

\[
\begin{align*}
\sigma_{xx}^{(1)} \nabla \psi_1 + \sigma_{xy}^{(1)} \mathbf{n} \times \nabla \psi_1 + g(\varphi_1 - \psi_1) &= 0, \quad (7)
\end{align*}
\]

\( i = 1, 2 \), where \( \mathbf{n} \) is a unit normal vector. [In Eq. (7) and below we use the units of \( e^2/h = 1 \).] To describe dc current, we seek a solution of Eqs. (6) on both edges of the bar with linear \( x \) dependence \( \varphi_i(x) = \varphi_i^{(0)} - \xi x \) which satisfies boundary conditions (7), where the functions \( \psi_{1,2} \) have a similar linear dependence. The current is calculated from this solution as a sum of the contributions from the bulk and both edges. After elementary but somewhat tedious algebra we obtain a relation \( I = 2i \int_0^\infty dx \frac{\psi_2(x) - \psi_1(x)}{x} \), where

\[
\frac{2}{\gamma} = \frac{\lambda w (\sigma_{xx}^{(1)} + \sigma_{xx}^{(2)})}{\rho_{xx}^{(1)} + \rho_{xx}^{(2)}} - \frac{\lambda w (\sigma_{xx}^{(1)} + \sigma_{xx}^{(2)})}{\sigma_{xx}^{(1)} + \sigma_{xx}^{(2)}} \frac{\gamma}{2},
\]

(8)

with \( w \) the bar width and \( \lambda = w g \gamma / (2\gamma + g) \). The quantities \( \sigma_{xx}^{(1,2)} \) are defined as \( \sigma_{xx}^{(1)} = \sigma_{xx}^{(1)} + \sigma_{xx}^{(2)} \). The quantity \( \gamma \), Eq. (8), replaces \( \gamma \) in Eq. (4). At vanishing bulk conductivity, \( \sigma_{xx}^{(1,2)} \to 0 \), we recover \( \gamma = \gamma \).

The Hall voltage can be calculated from this solution as \( V_H = \frac{1}{2} (\psi_1 + \varphi_2 - \varphi_1 - \varphi_2) \), where \( \varphi \) are variables at opposite edges. We obtain \( V_H = \xi E \), where
FIG. 4 (color online). Transport coefficients $\rho_{xx}$, $\rho_{xy}$ and $G_{xx} = \rho_{xx}/(\rho_{xx}^2 + \rho_{yy}^2)$, $G_{xy} = \rho_{xy}/(\rho_{xx}^2 + \rho_{yy}^2)$ for a Hall bar (Fig. 3), obtained from the edge model (6) with account of bulk conductivity [Eqs. (10), (8), and (9), see text]. The edge transport shunted by the bulk conduction away from $\nu = 0$ results in the $\rho_{xx}$ peak. Note the smooth behavior of $\rho_{xy}$ at $\nu = 0$, a tilted plateau in $G_{xy}$, and a double-peak structure in $G_{xx}$.

$$\xi = 2w \frac{\sigma_{xy}^{(1)}(\lambda + \sigma_{xy}^{(2)}) + \sigma_{xy}^{(2)}(\lambda + \sigma_{xx}^{(1)})}{2\sigma_{xx}^{(1)}\sigma_{xx}^{(2)} + \lambda\sigma_{xx}^{(2)} + \lambda\sigma_{xx}^{(1)}}. \quad (9)$$

This quantity vanishes at $\nu = 0$, since $\sigma_{xx}^{(1)} = -\sigma_{xx}^{(2)}$ and $\sigma_{xx}^{(1)} = \sigma_{xx}^{(2)}$ at this point due to particle-hole symmetry.

In Fig. 4 we illustrate the behavior of the longitudinal and transverse resistance, calculated from Eqs. (8) and (9), as

$$\rho_{xx} = w\bar{\gamma}/2, \quad \rho_{xy} = \xi\bar{\gamma}/2, \quad (10)$$

with $\gamma w = 6$, $gbw = 1$ [the omitted contact term (2) is small for these parameters]. Conductivities $\sigma_{xx}^{(1,2)}$, $\sigma_{xy}^{(1,2)}$ are microscopic quantities, and their detailed dependence on the filling factor is beyond the scope of this paper. Here we model the conductivities $\sigma_{xx}^{(1,2)}$ by Gaussians centered at $\nu = \pm 1$, $\sigma_{xx}^{(1,2)}(\nu) = e^{-A(\nu \pm 1)^2}$, as appropriate for valley-degenerate Landau level, whereby $\sigma_{xx}^{(1,2)}$ is related to $\sigma_{xx}^{(1,2)}$ by the semicircle relation [18]: $\sigma_{xx}^{(1,2)}(\sigma_{xx}^{(1,2)} + 2) + (\sigma_{xx}^{(1,2)})^2 = 0$. In Fig. 4 we used $A = 5$: however, we note that none of the qualitative features depend on the details of the model.

Figure 4 reproduces many of the key features of the data shown in Fig. 1. The large peak in $\rho_{xx}$ is due to edge transport near $\nu = 0$. The reduction in $\rho_{xx}$ at finite $\nu$ is caused by the bulk conduction short circuiting the edge transport. The latter corresponds to the double-peak structure in $G_{xx}$ in Fig. 4. We note that the part of $G_{xx}$ between the peaks exceeds the superposition of two Gaussians which represent the bulk conductivity in our model. This excess in $G_{xx}$ is the signature of the edge contribution. The transverse resistance $\rho_{xy}$ is nonzero due to imbalance in $\sigma_{xy}^{(1,2)}$ for opposite spin polarizations away from the particle-hole symmetry point $\nu = 0$. Notably, $\rho_{xy}$ does not show any plateau in the theoretical curve (Fig. 4), while $G_{xy}$ calculated from $\rho_{xy}$ and $\rho_{xx}$ exhibits a plateau-like feature. This behavior is in agreement with experiment (Fig. 1 and Ref. [14]).

To conclude, QH transport in graphene at $\nu = 0$ indicates presence of counter-circulating edge states dominating the longitudinal resistivity whereas the Hall resistivity is governed by bulk properties. Our model explains the observed behavior of transport coefficients, in particular, the peak in $\rho_{xx}$ and its field and temperature dependence, lending strong support to the chiral spin-polarized edge picture of the $\nu = 0$ state.
